**HHV8 and Kaposi’s sarcoma: a time cohort study**

**Abstract**

**Aims**—The recent finding that human herpes virus 8 (HHV8) is found in the majority of Kaposi’s sarcoma (KS) cases supports the epidemiological observation that the tumour may be caused by an infectious agent. This study aimed to address when and how HHV8 evolved.

**Methods**—A cohort of African endemic KS (49 samples from 45 patients) and European KS (18 samples from 13 patients), spanning 27 years, was assessed for the presence of HHV8 by both standard solution technique of TaqMan PCR and the newly described technique of TaqMan PCR.

**Results**—HHV8 was present in approximately 49% (24 of 49 tissue samples) of the African cases and in more than 90% (16 of 18 tissue samples) of the European cohort, in keeping with recent seroepidemiological data.

**Conclusions**—HHV8 is strongly linked to the development of KS; however, in some patients, other factors may operate. The utility and flexibility of TaqMan PCR in detecting low copy viral target in human tissues was demonstrated.

Keywords: human herpes virus 8; Kaposi’s sarcoma; polymerase chain reaction; TaqMan PCR

Kaposi’s sarcoma (KS) is a disease of uncertain histogenesis. While initially described in males of Eastern European Jewish and Mediterranean extraction (classic KS) the disease is now known to occur endemically in young African adult males and children. It is also seen in the context of immunosuppression (transplant associated) and HIV infection. Among the latter group, KS is an aggressive disease and serves as an AIDS defining illness. Epidemiological data indicate that in AIDS patients, KS is a disease largely confined to homosexual and bisexual males with low reported incidences in transfusion associated AIDS (3%) and haemophilia (1%). The cause of KS is unknown but the latter finding suggests that it may be caused by an infectious agent, possibly transmitted sexually. The most likely candidate is the newly described human herpes virus 8 (HHV8)—Kaposi’s sarcoma associated herpes virus (KSHV)—that appears to be associated with the vast majority of KS cases examined, including classic, African endemic, and AIDS associated forms.

Viral genetic analysis revealed that HHV8 is a y herpes virus with sequence homology to two other lymphomagenic viruses, Epstein Barr virus, and herpes virus saimiri. It has been categorised as a Rhadinovirus and is the only known member of this group to infect humans. The mode of acquisition of the virus is not known. It has been documented in peripheral blood mononuclear cells and its presence in semen suggests that the agent may be transmitted sexually. Seroepidemiological data indicate that HHV8 is not a ubiquitous infection, its distribution being largely restricted to high risk groups and inhabitants of endemic areas. Furthermore, there has been a dramatic increase in the incidence of KS with the advent of HIV infection, which raises the possibility that the two agents may be co-transmitted. How and when did HHV8 evolve? To help clarify this issue we investigated a cohort of African endemic KS (some originating in the 1960s) for the presence of HHV8 to determine whether there was a temporal association between HHV8 and KS.

**Materials and methods**

Forty nine KS samples (including 10 lymph nodes) were obtained from 45 Malawi patients. The material dated from 1968 to 1982 (table 1). The cohort comprised 38 males and five females, aged 18 months to 81 years. Clinical information was not available on two patients (one each from the 1970 and 1980 patient groups, respectively).

The tissue was paraffin wax embedded but the method of fixation was uncertain. None of the patients was HIV positive. Eighteen tissue samples from 13 cases of HIV positive European KS (eight males and five females) from the 1980s and 1990s were used as a control cohort.

**Solution Phase PCR**

Tissue ribbons (50 μm) were cut into sterile Eppendorf tubes observing anticontaminating procedures. Sections were de-waxed and suspended in 200 μl proteinase K digestion buffer (100 mM NaCl, 10 mM Tris, 25 mM EDTA, 0.5% SDS pH 8.4) containing 0.1 mg/ml of

*+, HHV8 positive.
*European HIV positive cases.
proteinase K, for three to five days at 37°C. Subsequent phenol-chloroform extraction and precipitation with 3 M sodium acetate/ethanol was performed. Samples were centrifuged and resuspended in high performance liquid chromatography (HPLC) water. The quality of extracted DNA was confirmed by β-globin amplification.

Nested primers amplifying the HHV8 open reading frame (ORF) 26 were employed:

**outer primers**—KS4 5'-AGCAGCTGCAGGGCAGTACG-3', KS5 5'-GACTCTTCGGCTGATGAACTGG-3';

**inner primers**—KS1 5'-AGCCGAAAGGGATTCACCAT-3', KS2 5'-TGGTGACTTCGTTCTACCTGAG-3'.

The following reaction conditions were employed: 0.5 μM each primer, 200 μM dNTPs, 1.5 mM MgCl2, 1 × PCR buffer (Perkin Elmer) and 2.5 units AmpliTaq DNA polymerase (Perkin Elmer). All reactions were performed in a 480 DNA thermal cycler (Perkin Elmer) with cycling parameters as follows:

**outer set**—94°C for 45 seconds, 60°C for 30 seconds, 72°C for 45 seconds, for 25 cycles;

**inner set**—94°C for 45 seconds, 55°C for 30 seconds, 55°C for 45 seconds, for 35 cycles.

A 94°C 30 second “hot start” was employed during both steps. Reaction products were visualised on an ethidium bromide stained 2% agarose gel (Sigma) (fig 1).

Positive cases were subsequently amplified with ORF 25 (HHV8 major capsid protein) as follows:

**outer set**—5'-AGGCAACGTCAGATGGAC-3', 5'-GAAATTACCACGGATGG-3';

**inner set**—5'-CATGGAGTACATTGTCAAGGACCTC-3', 5'-GGAATTACCTCGCAGGTGGG-3'.

Cycling parameters were as follows:

**outer primers**—94°C for 55 seconds, 55°C for 45 seconds, 72°C for 45 seconds, for 25 cycles;

**inner primers**—94°C for 55 seconds, 60°C for 45 seconds, 72°C for 45 seconds, for 35 cycles.

**SOUTHERN BLOTTING**

Following overnight transfer in 20 × SSC (3 M NaCl, 0.3 M sodium citrate pH 7.0) the filter was baked at 80°C for two hours and pre-hybridised for one to two hours in 5 × SSC, 1.0% blocking reagent (Boehringer Mannheim), 0.02% SDS, 0.1% sodium laurylsarcosine, 100 μg/ml sheared herring sperm DNA.

The filter was subsequently hybridised overnight with a biotin-labelled oligonucleotide probe (5'-TGTTGGTGAACATCTCATCTGAAAAATAT-3'). The filter was recovered, rinsed in 100 mM Tris-Cl (pH 7.5), 150 mM NaCl at room temperature followed by two stringency washes at 50°C (2 × SSC, 0.2% SDS). It was then placed for a further one to two hours in blocking solution at room temperature (100 mM Tris-Cl, 150 mM NaCl, 1% blocking reagent (Boehringer Mannheim); 0.5% Tween 20).

Streptavidin-alkaline phosphatase (Gibco BRL) was applied for 10 minutes (concentration 1 μg/ml in 100 mM Tris-Cl, pH 7.5, 150 mM NaCl) followed by three washes in 100 mM Tris-Cl, pH 7.5, 150 mM NaCl and a further rinse in 100 mM Tris-Cl, pH 9.5, 100 mM NaCl, 50 mM MgCl2. The filter was finally covered by NBT/BCIP (nitroblue tetrazolium/5-bromo-4-chloro-3-indolyl phosphate) and chromagen colour development monitored.

Rapid thermal ramp to 60°C—60°C for four minutes.

All sequencing was performed on the GeneAmp PCR system 9600 (Perkin Elmer).

Following purification (3 M sodium acetate/95% ethanol with a further rinse in 75% alcohol), the extension products were resuspended in HPLC water.

TaqMan PCR

TaqMan PCR is a newly described technique which allows direct detection of PCR product by exploiting the 5' nucleic activity of AmpliTaq DNA polymerase and the by the target specific release of a fluorescent reporter molecule during the PCR reaction (fig 2).

TaqMan PCR employs primer pairs as in conventional amplification as well as an oligonucleotide probe which consists of a fluorescent reporter dye (for example, FAM(6-carboxy-fluorescein)) at the 5' end and a 3' quencher dye (for example, TAMRA(6-carboxy-tetramethyl-rhodamine)). When the probe is intact the proximity of the reporter dye to the quencher dye is such that there is direct suppression of the fluorescence of the latter by Forster-type energy transfer.

During PCR, the probe will anneal specifically between the two primer pairs only if the target sequence is present. Because of the nucleic activity of AmpliTaq DNA polymerase, the probe is cleaved and reporter fluorescence released only if it is hybridised to its specific target. This obviates the need to perform gel analysis post-amplification.

The quantitative increase in reporter fluorescence can be detected reliably using a luminescence spectrometer (for example, Perkin-Elmer LS-50B). The magnitude of the generated signal (ΔRQ) represents the difference between the sample RQ (RQ+) and the no template control RQ (RQ−), where RQ = emission intensity of reporter divided by the emission intensity of quencher.

Using T distribution values it is possible to calculate a threshold ΔRQ above which samples are recorded as positive. It is mandatory to include at least three no template controls per microtitre plate assay. The design of target specific primers and probe was dictated by the nearest neighbour method which calculates the optimal annealing temperature under defined solution phase kinetics.

Extracted DNA was initially assessed by β actin PCR using the following protocol: 1× PCR buffer II (Perkin Elmer), AmpliTaqUNG (Perkin Elmer) 0.01 U/μl, 4 mM MgCl2, 200 μM dNTPs, 300 nM forward and reverse primers (forward 5'TCACCCACACTGTTGCCCATCTACGA-3', reverse 5'CAGCGGAACCGCTCATTGCCAATGG-3'), and 200 nM TaqMan probe (5'F-ATGCCCTCCCATGCAATCTCCGT-3' with the quencher TAMRA placed on base position 7 from the 5' end).

Samples were subsequently amplified for HHV8 (ORF26) as follows: 500 nM forward and reverse primers (KS1 5'AGCCGAAAGGATCCACATCAGATAGG-3', KS2 5'TCCGGTGTGGTCTAGCAG-3'), and 200 nM TaqMan probe (5'F-GCGTATTCTGCAGCCAGCTGTTGGTGTACCA-3', where F = FAM and T = TAMRA). No template controls were performed in triplicate.

ΔRQ sample values were estimated on the LS50B luminescence spectrometer (Perkin Elmer).

Results

Twenty two samples demonstrated the characteristic 233 base pair amplicon of HHV8 (ORF26) (fig 1). The product was confirmed on Southern blotting. An additional two cases were positive on TaqMan PCR (48.9%) (table 1).

Sixteen of the 18 European cohort amplified with both sets of primers with an additional case positive on TaqMan PCR (94%). All positive cases were sequenced (submitted for publication).

Table 1 summarises the patient demographic details and illustrates the number of positive cases by solution phase and TaqMan PCR. In the 1960 cohort, 10 of 14 samples (71.4%) were HHV8 positive. In the 1970–80 group (predominantly lymph node specimens) eight
of 16 (50%) specimens were positive. A lower prevalence rate is reported in the 1980–82 cohort (eight of 19) which may be a reflection of tissue fixation procedures rather than absence of HHV8 in the tissue. The 1984–95 group consisting of HIV-positive European male and female KS cases shows that 16 of 18 specimens contained HHV8 DNA sequences. TaqMan PCR yielded additional cases in the 1970–80 and 1981–82 cohorts as well as in the European group. Globally the results are in keeping with that reported by others and illustrate that HHV8 is present in KS biopsy samples from the 1960s (pre-AIDS). It also clearly delineates that HHV8 is an independent factor in the pathogenesis of KS, distinct from HIV.

Discussion

In recent years, much interest has focused on the pathogenesis of KS. Its cell of origin has been disputed as has the nature of the lesion—that is, whether it represents a true neoplasm. KS cell lines have been established which produce metastatic tumours in nude mice.

Epidemiological data suggests an infectious aetiology and, as early as 1972, Giraldo et al documented the presence of herpes-type viral particles in KS cell cultures from different geographic regions. Many candidate infectious agents have been proposed including human papilloma virus and human herpes virus 6, but none has been convincingly demonstrated. The recent discovery of a hitherto unknown herpes virus (HHV8) and its strong association with all forms of KS suggests that we may at last have found the elusive agent.

However, the pathogenesis of KS is an extremely complex process which involves cell adhesion molecules, cytokines, and cellular genes. Many groups have examined the role of cytokines which probably act in both a paracrine and autocrine fashion, including platelet derived growth factor, interleukin-6, and basic fibroblast growth factor (bFGF). It has also been demonstrated that the HIV Tat protein induces angiogenic lesions in nude mice and acts synergistically with bFGF. Whether this is triggered by an infectious agent such as HHV8 has yet to be elucidated.

It has been documented that there is increased expression of the anti-apoptosis gene Bcl-2 in both spindle and endothelial cells of KS but not in normal blood vessels. Another group has shown that Bcl-Xs, which also inhibits apoptosis, is expressed at a higher level than Bcl-2 in KS. CD40 expression has also been shown to be upregulated. This signalling molecule is known to be involved with cell surface antigen expression, B cell proliferation and differentiation, and inhibition of apoptosis. The Epstein Barr virus LMP-1 protein is known to enhance CD40 expression and it is possible that HHV8 may act in an analogous manner.

The accumulating data on HHV8 suggests that it is likely to be involved in the pathogenesis of KS. It has been described in the majority of examined KS lesions, and seroepidemiological data indicate that HHV8 infection parallels that of KS prevalence. Viral gene expression patterns suggest that it is present in latent form within the majority of infected cells and its pattern of expression is unlike that of other related herpes viruses. However, its documentation in a rare body cavity-based lymphoma and Castleman’s disease as well as in some non-HIV associated benign lymphoproliferative disorders does raise the possibility of it being a passenger virus. Alternatively, HHV8 may act as an oncoprotein virus operating in disparate tumour and reactive conditions. It has also been described in transplant associated squamous carcinomas even though this finding has been disputed by others.

The results presented here are important in many respects: a unique cohort has been assembled from 1968–95; PCR amplification systems amplifying regions within ORF 25 and ORF 26 have been used; the newly developed technique of TaqMan PCR (with an estimated detection sensitivity of one to five viral copies in 106 mammalian DNA sequences) has been employed; and the assembled patient groups revealed geographical differences, in that the 1968–82 group was from Malawi (Central Africa), the later group (1984–95) European.

The finding of 49% HHV8 positivity in the African case cohort reflects the high prevalence of endemic KS in Africa. The data parallels seroepidemiological findings which have recently been published, documenting sero-prevalence rates of approximately 50% in mid-African locales. The higher prevalence rates in male and female HIV positive European KS cases again reflects seroepidemiology data for such cohorts. Thus, there is overall agreement between serology and PCR data presented here, for the cohorts studied.

Our results suggest that HHV8 may not always be implicated in the pathobiology of KS. It is possible that while the virus acts as an initiator in the inflammatory cascade, it may be lost as the lesion progresses. An additional consideration is that the virus may mutate over time with genetic divergence from currently known HHV8 sequences, and thus may not be amplified using current sequence primer designs. In any event, the exact mechanism of action of HHV8 in KS has not been fully elucidated. Clearly, the development of KS lesions is dependent on a complex interplay between inflammatory mediators and apoptosis genes with or without an initiating infectious agent.

The authors thank the Malawi Ministry of Health.
